# 1 Introduction

**Goal:** increase the Dice score from  $\sim 90\%$  to  $\geq 95\%$ .

**Dataset:** 1020 images (target  $\sim 5820$ ).

This document lists proposed improvements to the U-Net++ segmentation model, grouped by priority and by the effort required, together with the estimated impact on the Dice score and the implementation difficulty.

## 2 Critical Improvements - Immediate Implementation

| Change                                         | Why                                                                                                                                                                                           | Est. impact | Difficulty |
|------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------------|------------|
| Fix the <code>val_dataset</code> transform bug | The current code overrides the transforms for the whole dataset (including training), so validation does not work correctly. Fixing it yields reliable metrics and improves training quality. | +1-3%       | Easy       |
| Dice + Focal Loss or Tversky Loss              | Focal Loss focuses on hard pixels (disc/cup boundaries). Tversky lets you weight FP and FN separately - clinically important (missing glaucoma costs more than a false alarm).                | +1-3%       | Easy       |
| Mixed Precision Training (AMP)                 | float16/float32 training allows raising the batch size from 8 to 16-24. Larger batches stabilise Batch Normalization in the encoder - a direct Dice increase.                                 | +1-2%       | Easy       |

## 3 Important Improvements - New Training / Inference

## 4 Additional Improvements - After Dataset Expansion

## 5 Combined Potential

Implementing the improvements from Sections 2 and 3 should be enough to reach  $\geq 95\%$  Dice. Section 4 becomes relevant after the dataset is expanded to  $\sim 5820$  images.

## 6 Summary

The critical fixes (validation transform, loss function, AMP) are low-effort, high-value and should be applied immediately. Combined with the important training/inference changes,

| Change                                | Why                                                                                                                                                                                                  | Est. impact | Difficulty |
|---------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------------|------------|
| Test-Time Augmentation (TTA)          | Predict on several versions of the image (flip, rotation) and average. No retraining - removes random segmentation artefacts; results are more consistent and reproducible.                          | +0.5-1.5%   | Easy       |
| CLAHE + fundus-specific augmentations | CLAHE is a standard preprocessing step in ophthalmology - it equalises contrast locally and sharpens disc boundaries. RandomGamma simulates different fundus cameras. Crucial for multi-clinic data. | +1-2%       | Medium     |
| Cosine Annealing + Linear Warmup      | The current ReduceLROn-Plateau is reactive. Warmup protects the encoder's pretrained weights; the cosine LR decay improves the model's final fit.                                                    | +0.5-1%     | Easy       |
| K-Fold CV (5 folds) + Ensemble        | With 1020 images a single split is too little ( $\sim 200$ val). 5-Fold gives a reliable estimate plus 5 models for an ensemble, which when averaged consistently beats a single model.              | +1-2%       | Medium     |

they are expected to reach the  $\geq 95\%$  Dice target on the current dataset; the additional changes pay off once the dataset is expanded.

| Change                                                        | Why                                                                                                                                                                        | Est. impact | Difficulty |
|---------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------------|------------|
| Morphological post-processing                                 | Closing fills holes in the masks; Connected Components removes artefacts. Anatomical constraint: the cup must lie inside the disc - this can be enforced programmatically. | +0.5-1%     | Medium     |
| Change the encoder (EfficientNet-B5 / ConvNeXt-Base / MiT-B3) | With 5820 images a larger/newer encoder will no longer overfit. MiT-B3 (SegFormer) is designed specifically for medical segmentation.                                      | +0.5-2%     | Easy       |

| Stage                                               | Total estimated gain                           |
|-----------------------------------------------------|------------------------------------------------|
| Section 2 - Critical (1020 images)                  | +3-8% Dice                                     |
| Sections 2 + 3 - Critical + Important (1020 images) | +5-10% Dice $\rightarrow \geq 95\%$ achievable |
| Sections 2 + 3 + 4 (5820 images)                    | +6-13% Dice $\rightarrow$ full optimisation    |
